

The Photonic Holonet

A Single Self-Entangled Photon as Universal Computer, Universal Network, and Clock
on the $W(3,3)$ Substrate

Wil Dahn

June 2026 — machine-verified edition

Abstract

We present a complete, machine-verified architecture in which one self-entangled photon, traversing one finite geometry, is simultaneously the hardware, the software, and the network of a universal quantum computer. The geometry is the symplectic generalized quadrangle $W(3,3)$: forty points, forty lines, automorphism group $\text{Sp}(4, \mathbb{F}_3)$ of order 51840. The photon carries $W(3,3)$ twice over — once as the forty Witting rays of its path-polarization space $\mathbb{C}^4$ (states), once as the forty Pauli displacement classes of its past-future time-bin space $\mathbb{C}^9$ (operators) — and the two carriers realize the same incidence geometry, making the machine’s states and gates one set of objects. Every architectural layer is a theorem with an executable witness: the preparation circuit (two Clifford gates of tabletop optics), the routing fabric (an atlas of 540 hypercube charts glued along the 1620 apartments of the Tits building), the protected memory (the Steinberg module of dimension 81), the mirror middleware (a 2160-slot D_{12} transport bus whose full Clifford lift factors as $24 \cdot 45 \cdot 48 = 51840$), the fuel (the matter shell is exactly the magic sector, with exact Kochen–Specker budget $36/40$ and contextual fraction $1/10$), the clock (an internal $\mathbb{Z}_{12}$ gauge clock, two external references $\mathbb{Z}_7, \mathbb{Z}_{13}$, and an irrational Boerdijk–Coxeter drive realizing a discrete time quasicrystal), and universality (the photon’s own tritter, phase plate, and modulator generate the complete Clifford group; the matter shell supplies the magic). We also give the recursive engineering law: a level- n holonet has 40^n photonic leaves, $(40^n - 1)/39$ $W(3,3)$ instances, and reversible routing diameter bounded by $8n = 8 \log_{40} N$, while durable commits use a separate Császár/tomotope clock $T(n) = 4(7^n - 1)$. The newest runtime layer turns the tomotope cover pathology into an engineering feature: durable storage is cover-indexed by a $\mathbb{Z}_k^3$ fiber over the stable 48-block packet ABI, sentinel-aware compilation can trade commit-time slack for lower $g = 15$ fault energy, the first exact guard band is the arithmetically forced desynchronization at $n = 5$ with remainder $24 = f$, and the Grünbaum–Coxeter Wythoff operations of the tomotope are exactly the packet-growth ladder 4, 12, 24, 48, 96. No fitted parameters appear anywhere: every constant is substrate arithmetic at $q = 3$.

1 Overture: the machine is the geometry is the carrier

Classical architecture separates three things: the processor that acts, the program that directs, and the network that connects. The thesis of this paper is that at the level of a single photon on a finite symplectic geometry the three are one object, and that this is not a metaphor but a chain of theorems.

Principle 1.1 (Identity of the three layers). *Transporting the photon through the mesh is applying a gate is routing a packet. One physical process; three descriptions.*

The identification rests on five exact pillars, each proved by explicit computation in the project repository (every theorem below carries its witness script):

1. **Operator–operand duality** (§2.1): the same $W(3, 3)$ is drawn by the photon’s *states* (orthogonality of the 40 Witting rays in $\mathbb{C}^4$) and by its *operators* (commutation of the 40 two-qutrit Pauli classes on $\mathbb{C}^9$).
2. **Routing–gate identity** (§4): the mesh is an atlas of 540 three-dimensional hypercube charts whose native XOR routing moves are exactly the register operations, glued along the 1620 apartments of the Tits building of $\mathrm{Sp}(4, \mathbb{F}_3)$.
3. **Mirror middleware** (§5): the cyclic selector clock and the mirror transport bus are different 2160 worlds. The photon is clocked by the C_{12} side but routed by the D_{12} side, whose full Clifford lift is the exact product $24 \cdot 45 \cdot 48$.
4. **Universality from optics** (§6.5): the photon’s own beam-splitting elements generate the complete Clifford group (symplectic closure = 51840, exact), and its matter shell is precisely its magic supply.
5. **Fractal holonet scaling** (§7): recursively replacing every site by a fresh $W(3, 3)$ core gives a universal computer/network with exact 40^n leaves and logarithmic reversible routing.

One loop: carrier $\rightarrow$ data plane $\rightarrow$ router $\rightarrow$ building $\rightarrow$ runtime $\rightarrow$ tomatope packet $\rightarrow$ mirror bus $\rightarrow$ carrier.

Figure 1: The photonic holonet as an engineering stack. The same photon is data, instruction, and packet; the same finite geometry supplies the network, middleware, and runtime.

2 The substrate

Definition 2.1 ($W(3, 3)$). *Let $V = \mathbb{F}_3^4$ with the alternating form $\langle u, v \rangle = u_1v_3 - u_3v_1 + u_2v_4 - u_4v_2$. The points of $W(3, 3)$ are the 40 projective points of V ; the lines are the 40 totally isotropic projective lines. Each point lies on 4 lines and each line carries 4 points; collinearity defines the strongly regular graph $\mathrm{SRG}(40, 12, 2, 4)$.*

The full automorphism group is $\mathrm{Sp}(4, \mathbb{F}_3)$, of order $51840 = |W(E_6)|$, acting with permutation rank 3. The substrate primitives are

$$q = 3, \quad \lambda = 2, \quad \mu = 4, \quad k = 12, \quad f = 24, \quad g = 15, \quad \Phi_6 = 7, \quad \Phi_4 = 10, \quad \Phi_3 = 13,$$

and every numerical claim in this paper reduces to arithmetic in these.

Formal grounding (the master formalism). In the master manuscript [1] the whole structure is forced by one Diophantine seed: the *master equation* $q! = 2q$ has the unique positive-integer solution $q = 3$, and the SRG quadratic $x^2 - q!x + 2^q = (x - 2)(x - 4)$ then delivers $\lambda = 2$, $\mu = 4$ and the full parameter closure ($k = 2^q + q + 1$, $v = 40$, multiplicities $f = 24$, $g = 15$, cyclotomic ladder $\Phi_3 = 13$, $\Phi_6 = 7$, $\Phi_{12} = q^4 - q^2 + 1 = 73$, $\Theta = q^2 + 1 = 10$). Two of those closure constants

reappear in this paper as *spectral field discriminants*: the chart-web’s irrational eigenvalue pairs $1 \pm \sqrt{10}$ and $(-1 \pm \sqrt{73})/2$ (§4) live precisely in $\mathbb{Q}(\sqrt{\Theta})$ and $\mathbb{Q}(\sqrt{\Phi_{12}})$ — the machine’s transport spectrum speaks the same cyclotomic dialect as the physics tier ladder.

2.1 The two carriers and the operator–operand duality

Theorem 2.2 (Two realizations, one geometry). (i) *The 40 Witting rays in $\mathbb{C}^4$ (the photon’s path $\otimes$ polarization space) have orthogonality graph isomorphic to the collinearity graph of $W(3, 3)$.* (ii) *The 40 projective classes of two-qutrit Pauli displacements $D(v) = X^a Z^b \otimes X^c Z^d$ on $\mathbb{C}^9$ (the photon’s past $\otimes$ future time-bin space) have commutation graph equal to the same $W(3, 3)$, via $D(u)D(v) = \omega^{\langle u, v \rangle} D(v)D(u)$. Witnesses: `bt817_self_entangled_photon_atlas.py`, `bt821_operator_operand_duality.py`.*

Thus a point of the substrate is simultaneously a pure state the photon can occupy and a unitary the photon can enact; a line is simultaneously a measurement context (orthonormal tetrad) and a stabilizer group (maximal commuting Pauli set with its 9-state joint eigenbasis). The $360 = 40 \times 9 = f \cdot g$ two-qutrit stabilizer states are the joint eigenbases of the forty lines.

2.2 The five vacua and the Schläfli geography

Every maximal subgroup class of $\mathrm{P}\mathrm{Sp}(4, 3)$ decomposes the substrate in its own canonical way; the maximal indices are the classical inventory of the 27 lines on a cubic surface.

index	subgroup	points	lines	vacuum	cubic surface
27	$2^4:A_5$	[40]	[40]	homogeneous (icosahedral)	27 lines
36	S_6	[40]	[10, 30]	spread fibration	36 double-sixes
40	parabolic	[1, 12, 27]	[4, 36]	holonet point vacuum	trihedra I
40	parabolic	[4, 36]	[1, 12, 27]	dual line vacuum	trihedra II
45	$(2T \times 2T):2$	[8, 32]	[16, 24]	binary polar	45 tritangents

The physical decomposition $40 = 1 + 12 + 27$ (self + gauge shell + matter shell) is the *choice of the point-parabolic vacuum* among five inequivalent readings; the icosahedral vacuum sees a featureless substrate. The platonic ladder threads the table: the binary tetrahedral group $2T$ (the 24-cell) lives in every polar-pair stabilizer, the real octahedral group $O_h (= S_4 \times \mathbb{Z}_2, \text{order } 48)$ is the chart symmetry of §4, and the binary icosahedral group $2I = \mathrm{SL}(2, 5)$ (the 600-cell) is the core of every spread stabilizer, with point orbits [20, 20] and line orbits [10, 30] echoing the Boerdijk–Coxeter decomposition $600 = 20 \times 30$. *Witnesses: bt808–bt813.*

3 The carrier: how to self-entangle a photon

Entanglement is a relation between tensor factors; nothing requires the factors to be distinct particles. Self-entanglement is entanglement between one photon’s own registers.

3.1 Stage A: spatial (one element)

A diagonal photon meets a polarizing beam splitter: $\frac{1}{\sqrt{2}}(|H\rangle + |V\rangle) \mapsto \frac{1}{\sqrt{2}}(|H, a\rangle + |V, b\rangle)$. Path and polarization are now maximally entangled *within* the photon; this two-qubit $\mathbb{C}^4$ is the Witting carrier of Theorem 2.2(i).

3.2 Stage B: temporal (two Clifford gates)

A tritter (symmetric 3-port coupler) is the qutrit Fourier gate F_3 ; a three-bin delay ladder $(0, \tau, 2\tau)$ defines past and future registers; one electro-optic modulator applies $CX_{p \rightarrow f}$ conditioned on bin index. The temporal Bell qutrit

$$|\Omega\rangle = CX_{p \rightarrow f}(F_3 \otimes I)|0\rangle_p|0\rangle_f = \frac{1}{\sqrt{3}} \sum_{j=0}^2 |j\rangle_p |j\rangle_f$$

is verified exactly; the photon is entangled with its own future. Inserting any U in the future arm, the recombination visibility is the *trace-Choi witness*

$$V(U) = \frac{|\text{Tr } U|}{3}, \quad V(F_3) = \frac{1}{3}, \quad V(X) = V(Z) = 0,$$

so the photon implements the Choi–Jamiołkowski isomorphism on itself: it measures channels against its own past. *Witness: bt820_self_entanglement_protocol.py.*

Figure 2: Preparation schematic. One photon, four registers. The PBS entangles path with polarization (Stage A); the tritter–delay–EOM chain prepares the temporal Bell qutrit $|\Omega\rangle$ (Stage B); the dashed loop is the irrational Boerdijk–Coxeter drive of §11.

4 The network: atlas, building, and routing

Theorem 4.1 (The hypercube atlas). *$W(3,3)$ contains exactly 540 skew line pairs. For each pair the non-collinearity graph on its 8 points is the cube graph Q_3 , with full symmetry group O_h of order 48 (these are the only order-48 stabilizers; the binary $2O$ does not occur). Each chart admits an exact $\mathbb{F}_2^3$ Gray-code addressing in which chart edges are unit XOR moves and the antipode of a vertex is its unique collinear partner. Every $W(3,3)$ nonedge is a chart edge in exactly $12 = k$ charts; every edge is an antipode pair in exactly $9 = q^2$. Witnesses: bt773, bt777, bt778.*

4.1 Hypercube networking, not hypercube decoration

The cube is not only a picture for one chart. It is the local interconnect primitive. A chart gives eight simultaneously valid addresses

$$000, 001, 010, 011, 100, 101, 110, 111 \in \mathbb{F}_2^3,$$

and the elementary network instruction is the dimension-order hypercube hop

$$a \longmapsto a \oplus e_i, \quad i \in \{1, 2, 3\}.$$

This is the standard e-cube rule of hypercube networks: compare source and target, flip one differing coordinate at a time, and finish in at most three local hops [6]. In the holonet that same XOR flip is also a register operation, because the chart address is a finite “which-register” word on the photon’s self-entangled carrier. The local routing primitive is therefore simultaneously

$$\text{bit flip} = \text{qutrit-frame update} = \text{optical path choice}.$$

A packet in the photonic holonet is not merely a payload. The natural packet header is

$$\mathcal{P} = (\text{payload}, \text{Pauli frame}, \text{chart word}, \text{apartment hop}, \text{mirror slot}, \text{clock phase}).$$

The payload is the quantum state or teleported gate; the Pauli frame is the two-trit feedforward record; the chart word is the $\mathbb{F}_2^3$ route inside the current cube; the apartment hop selects the next chart; the mirror slot chooses the D_{12} transport bus of §5; and the clock phase is the cyclic C_{12} interrupt that keeps the selector coherent. This is why the same object can be called a computer architecture and a network architecture. A node never sends data to a processor: the act of transport is the processor’s gate action.

Theorem 4.2 (The fabric is the building). *The chart-adjacency web (540 nodes, two charts adjacent when one’s axis is a disjoint transversal pair of the other) is 6-regular with exactly 1620 edges, and these edges are in canonical bijection with the 1620 apartments of the Tits building of $\text{Sp}(4, \mathbb{F}_3)$. The web has diameter 5; its adjacency module contains the Steinberg representation twice and presses against the Ramanujan bound only on a 15-dimensional sentinel eigenspace. Witnesses: bt777, bt779, bt744.*

Figure 3: Network schematics. Left: a single chart with its $\mathbb{F}_2^3$ addressing (XOR routing native). Center: the 540-chart web whose links are the apartments of the Tits building (sketched as a circulant fragment). Right: the two-level routing stack.

Routing a packet means choosing XOR moves inside charts and apartment hops between them; since chart moves *are* register operations (§6), routing is computation. At scale the recursion is the holonet ladder: 40^n cores at level n , the same $\text{SRG}(40, 12, 2, 4)$ at every level, with the level-0 chart’s $1 + 12 + 27$ degree split realized as self pole, gauge shell, and matter shell of each node.

Corollary 4.3 (Two-plane routing bound). *Inside a chart the worst route length is 3, the diameter of Q_3 . Between charts the worst route length is 5, the diameter of the apartment web. One recursive digit of a holonet address therefore costs at most*

$$3 + 5 = 8$$

reversible transport moves. BT827 globalizes this to $8n = 8 \log_{40} N$ for $N = 40^n$ photonic leaves.

5 The middleware: toмотope mirrors and the runtime bus

Definition 5.1 (Tomotope packet). *In this paper the toмотope is used in the only way the finite calculation currently justifies: as a local middle-layer incidence packet. A toмотope packet has four vertex carriers, twelve local edge axes, sixteen triangular face labels, and forty-eight edge-face incidence blocks. The doubled base/shadow fiber gives 192 flags. Thus the toмотope is the durable packet format sitting between the fast cube router and the global mirror bus; it is not introduced as an ambient continuous torus, and it is not identified with the rectangle clock.*

The atlas contains two different 2160-element boundary worlds. They must not be collapsed. The rectangle side is cyclic: its stabilizer is C_{12} and it supplies the selector's phase clock. The chart-transversal side is dihedral: its stabilizer is D_{12} and it supplies the mirror transport bus. Equal cardinality is the red herring; different stabilizer structure is the theorem.

Theorem 5.2 (The D_{12} mirror bus). *The 540 cube charts carry exactly four common-transversal slots each, so the global chart-transversal space has $540 \cdot 4 = 2160$ slots. The map*

$$(\text{chart, common transversal line}) \mapsto (\text{chart, antipode pair cut out by that transversal})$$

is an equivariant bijection onto the atlas antipode-slot space. Its projective stabilizer has order 12 and GAP identifies it as D_{12} , not C_{12} . Witness: `bt815_global_2160_transversal_gset.py`.

Locally, a skew-line chart has four common isotropic transversals. Read those four transversals as the four vertex carriers of the toмотope middle layer. Each transversal is a K_4 , and each K_4 has three opposite-edge axes and four triangular faces. Thus the chart carries

$$4 \text{ vertices,} \quad 4 \cdot 3 = 12 \text{ edge labels,} \quad 4 \cdot 4 = 16 \text{ face labels,}$$

and the middle incidence packet has

$$4 \cdot 3 \cdot 4 = 48$$

edge-face blocks, with the doubled base/shadow fiber restoring 192 flags. This is the local $\langle r_0, r_3 \rangle$ toмотope block layer, not an analogy to a toroidal polyhedron. *Witness: `bt814_tomotope_middle_layer_from_residual_tetrahedra.py`.*

Theorem 5.3 (Photonic mirror middleware). *The full optical Clifford runtime factors as*

$$|\text{Sp}(4, \mathbb{F}_3)| = 51840 = 24 \cdot 2160 = 24 \cdot 45 \cdot 48.$$

Here $24 = f$ is the full $\text{Sp}(4, 3)$ lift of the projective D_{12} mirror-slot stabilizer, 45 is the hyperbolic polar-pair/tritangent geography, and 48 is the local toмотope edge-face middle layer (also the order of the chart group O_h). Equivalently, the photon is clocked by the cyclic selector side and routed by the dihedral mirror side; the complete Clifford group is the lift of that mirror bus through the toмотope middle carrier. Witness: `bt826_photonic_mirror_middleware.py`.

This is the architectural closure missing from a bare universality claim. The tritter, phase plate, and controlled delay generate the whole Clifford group, but the group is *organized* as a middleware stack: full slot stabilizer, global mirror bus, polar vacuum geography, and toмотope local block. In software terms, C_{12} is the clock interrupt, D_{12} is the mirror router, 48 is the local packet format, and $24 \cdot 45 \cdot 48$ is the finite runtime.

fast XOR routing is committed through the tomotope middle layer and reflected by the mirror bus.

Figure 4: Middleware schematic. The cube is the reversible local router; the tomotope is the edge-face packet format; the D_{12} bus is the global mirror transport object.

6 The software: braids, teleported gates, universality

6.1 Exact braid words

In the anyonic Fibonacci representation $\sigma_1 = \text{diag}(\zeta^4, -\zeta^2)$ ($\zeta = e^{i\pi/5}$) one has *exactly* $\sigma_1^5 = Z$ and $\sigma_1^{10} = I$ — not merely projectively (verified in the cyclotomic ring $\mathbb{Z}[\zeta_{10}]$). In the dual ($\pm$) encoding of the local $K_{3,3}$ cycle code $\mathbb{F}_2^4$ this makes every register bit-flip an exact five-letter braid word, and the flat global register (the unique connected gluing with trivial holonomy across the atlas) carries the action coherently: a zero-Berry-phase memory. *Witnesses: bt740, bt741.*

6.2 The photon is its own gate

A gate U is stored as the self-entangled state $(I \otimes U)|\Omega\rangle$; Bell-projecting an input register against the photon’s *past* register outputs U (times a known Pauli correction) on the *future* register — verified for all nine outcomes. The machine’s gate library is a library of self-entangled states; executing software means interfering the photon with its own history. *Witness: bt821.*

6.3 Instruction set architecture

The practical instruction set is finite:

$$\mathcal{I}_{\text{holo}} = \{F_p, F_f, S_p, S_f, CX_{p \rightarrow f}, \sigma^5 = Z, D_{12}\text{-mirror}, M_{36}\text{-magic}\}.$$

F and S generate single-qutrit Clifford frame changes; CX couples past to future; $\sigma^5 = Z$ gives exact braid-register flips; the D_{12} mirror operation moves a packet through the atlas without confusing it with the cyclic selector clock; and M_{36} denotes injection from the thirty-six magic rays of §9. The Clifford part normalizes Pauli frames and is efficiently classically trackable; it is not universal by itself. Universality starts only when the Clifford runtime can consume the intrinsic magic sector. This is the engineering meaning of “matter equals magic”: the same thirty-six rays that appear as the matter shell are the non-Clifford fuel for the processor.

6.4 The minimal classical shadow

The smallest classical headline compatible with the substrate is the pair

$$(\lambda, q) = (2, 3).$$

This is the same two-state, three-symbol signature made famous by the Wolfram–Smith weakly universal Turing machine. The present paper does not use that result as the proof of quantum

universality; the proof is the Clifford closure plus magic/contextuality [8, 7]. The point is sharper: the classical shadow of the photonic holonet lands on the same minimality boundary. The quantum machine has forty rays and an $81 = q^4$ protected register, but its smallest visible finite-state control alphabet is already the substrate pair 2, 3.

6.5 The Universality Theorem

Theorem 6.1 (Clifford completeness from optics). *The symplectic images of the photon’s physical elements — the tritter F_3 on either register, the quadratic phase plate S , and the delay-conditioned CX — generate all of $\text{Sp}(4, \mathbb{F}_3)$ (closure of order 51840, exact). Hence tabletop optics realize the complete two-qutrit Clifford group modulo Paulis and phases. Witness: `bt825_universality_theorem.py`.*

Theorem 6.2 (Universality). *Clifford completeness, together with the machine’s intrinsic magic supply (§9) and the strict positivity of its contextual fraction (1/10, exact), implies universal quantum computation by magic-state injection; for qutrits, contextuality is necessary and sufficient for magic distillation (Howard–Wallman–Veitch–Emerson) [3]. One self-entangled photon on the $W(3, 3)$ mesh is a universal quantum computer whose transport is its gate action.*

7 Fractal scaling: the computer is the network

The single-core theorem is not the end of the architecture. The substrate is self-similar: any node may be replaced by a fresh copy of the same forty-node holonet, with the parent line/point incidence becoming the routing grammar for the child layer.

Definition 7.1 (Recursive holonet). *Let $\mathcal{H}_0$ be one self-entangled photonic qutrit. Define $\mathcal{H}_n$ recursively by replacing each point of one copy of $W(3, 3)$ with a copy of $\mathcal{H}_{n-1}$. Thus $\mathcal{H}_1$ is the single-core machine of this paper and $\mathcal{H}_n$ is a 40-ary fractal computer/network.*

Theorem 7.2 (BT827 holonet scaling law). *A level- n holonet has*

$$N_n = 40^n$$

photonic leaf cores and

$$I_n = 1 + 40 + \cdots + 40^{n-1} = \frac{40^n - 1}{39}$$

total $W(3, 3)$ instances. Its total edge-qutrit slots are $240I_n$, its directed transport slots are $480I_n$, its chart routers are $540I_n$, its apartment links are $1620I_n$, its mirror slots are $2160I_n$, and its local Clifford runtime atoms are $51840I_n$. Worst-case reversible routing across the recursive address uses at most

$$8n = 8 \log_{40} N_n$$

moves, where $8 = 3 + 5$ is one in-chart hypercube diameter plus one chart-web apartment diameter. Durable commits use the distinct Császár/tomotope clock

$$T(0) = 1, \quad T(g) = 4(7^g - 1) \quad (g \geq 1).$$

Witness: `bt827_holonet_fractal_architecture.py`.

level n	leaves 40^n	$W(3,3)$ instances	mirror slots	runtime atoms	route bound
1	40	1	2160	51840	8
2	1600	41	88560	2125440	16
3	64000	1641	3544560	85069440	24
4	2560000	65641	141784560	3402829440	32

Figure 5: Fractal scaling schematic. The drawn fans show only a few children; the rule is exact substitution of forty child holonets at each substrate point. Routing grows logarithmically in the number of photonic leaves because each recursive digit costs at most eight reversible moves.

This resolves the computer-engineering question. A conventional machine grows by adding processors connected by a separate network. The holonet grows by adding copies of the same object; each copy contains its own processor, router, memory, clock, and packet format. There is no von Neumann bus to saturate. At every scale, the edge set is both communication bandwidth and entangling-gate availability, the chart atlas is both routing table and instruction decoder, and the Steinberg 81-sector is both protected memory and fault-tolerant logical space.

8 Runtime closure: compile, monitor, commit

The architecture now has an executable operating-system loop.

address word $\longrightarrow$ packet route $\longrightarrow$ sentinel monitor $\longrightarrow$ durable tomatope commit.

BT828–BT831 make each arrow finite and testable.

Theorem 8.1 (BT828 packet compiler). *A recursive address word with digits in $\{0, \dots, 39\}$ compiles to a sequence of digit packets*

(Q_3 -XOR hops, apartment hops, D_{12} mirror slot, C_{12} phase, tomatope block).

Each digit uses at most three XOR hops and at most five apartment hops, hence at most eight reversible moves. The stress route

$$(0, 7, 14, 21, 28, 35) \longrightarrow (39, 32, 25, 18, 11, 4)$$

compiles to 47 reversible moves, below the level-six bound 48. Witness: `bt828_holonet_packet_compiler.py`.

Theorem 8.2 (BT829 sentinel monitor). *The projector onto the $g = 15$ adjacency sector of $W(3, 3)$ has exact entry profile*

$$P_{-4}(x, x) = \frac{3}{8}, \quad P_{-4}(x, y) = \begin{cases} -\frac{1}{8}, & x \sim y, \\ \frac{1}{24}, & x \approx y. \end{cases}$$

Consequently a full context line K_4 is sentinel-invisible, while localized, mirror, and shell faults activate the sentinel with exact energies:

<i>fault</i>	<i>energy</i>	<i>normalized fraction</i>
<i>single point</i>	3/8	5/13
<i>adjacent edge</i>	1/2	5/19
<i>nonedge mirror pair</i>	5/6	25/57
<i>gauge shell $N(x)$</i>	6	5/7
<i>matter shell</i>	27/8	5/13

The immune system is therefore not generic noise detection: it is blind to legal context-line traffic and tuned to off-context routing and shell congestion. Witness: `bt829_fault_sentinel_monitor.py`.

Theorem 8.3 (BT830 two-phase commit clock). *The runtime has two clocks. The reversible prepare phase finishes in at most $8n$ moves. The durable commit phase waits for*

$$T(n) = 4(7^n - 1).$$

For $1 \leq n \leq 24$, $T(n)$ is always divisible by 24 and by 8, so it is aligned with both the local runtime stabilizer and the single-digit route window. But it is not always divisible by the full $8n$ route epoch: the first desynchronization is $n = 5$, with remainder $24 = f$. Thus the commit layer is deliberately slower and cover-like; it is not merely the route clock renamed. Witness: `bt830_two_phase_commit_clock.py`.

8.1 The infinite-cover warning

The tomatope contributes a harder boundary than the earlier packet picture showed. Monson, Pellicer, and Williams prove that the tomatope has infinitely many distinct minimal regular covers; for coprime odd $p, q > 1$ there are minimal covers R_p, R_q of the tomatope such that neither covers the other, and neither covers the special R_2 cover [11]. They also record the toroidal cover arithmetic

$$|\text{Mon}(Q_k)| = 36864 k^6, \quad Q_k : (4, 24, 32, 8, 4)k^3$$

for vertices, edges, triangles, tetrahedra, and octahedra.

Architecturally this is a big correction. The 48-block tomatope middle layer is a stable local ABI, but the global regular cover is not unique. Durable storage must therefore carry a *cover index* k as an implementation gauge. Fast routes compile to the same invariant packet, while persistent storage may choose one minimal cover family without invalidating the other non-comparable families. *Witness: `bt831_tomotope_minimal_cover_architecture.py`.*

8.2 Cover-indexed storage, rerouting, and guard bands

The infinite-cover warning would be useless as engineering unless it changed the runtime. BT832–BT834 make it operational. The principle is that the local tomatope packet is the ABI and the chosen regular cover is the storage backend.

Theorem 8.4 (BT832 cover-indexed durable storage). *For every supported cover index k , durable storage is the lifted packet space*

$$\{0, \dots, 47\} \times \mathbb{Z}_k^3, \quad |\text{slots}| = 48k^3,$$

with projection back to the fast-route ABI by forgetting the $\mathbb{Z}_k^3$ coordinate. The kernel to the base tomospace packet has order

$$k^6 = (k^3)^2,$$

matching the Monson–Pellicer–Williams toroidal cover law $|\text{Mon}(Q_k)| = 36864k^6$. Changing k changes durable capacity and kernel size, but not the packet program seen by the compiler. Tested cover gauges $k = 3, 5, 7, 11, 13$ all reduce exactly to the same 48-block ABI, and larger k reduces the load fraction of the same stress program. Witness: `bt832_cover_indexed_durable_storage.py`.

Theorem 8.5 (BT833 sentinel-aware packet rerouting). *The BT829 projector supplies a compiler-visible cost function. Before the durable commit, each digit route may insert up to two W33 waypoint points and minimize*

sentinel energy first, reversible move count second.

The extra reversible moves are charged to the slower BT830 commit phase, not to the BT827 fast $8n$ route bound. In the level-six stress program the direct route uses 47 moves and total sentinel energy 4; the sentinel-aware route uses 58 moves, still far below the 470592-tick commit window, and lowers the total sentinel energy to 2. Each tested digit route strictly lowers its own $g = 15$ energy; adjacent endpoints can be context-completed to zero, and nonedge mirror pairs drop below their direct $5/6$ activation. Witness: `bt833_sentinel_aware_packet_rerouter.py`.

Theorem 8.6 (BT834 desynchronization guard-band arithmetic). *The two-phase clock has an exact number-theoretic boundary. Full route-epoch synchronization is*

$$8n \mid T(n) = 4(7^n - 1),$$

equivalently

$$2n \mid 7^n - 1.$$

For every odd prime power $p^a \mid n$ with $p \neq 7$, this requires $\text{ord}_{p^a}(7) \mid n$; if $7 \mid n$, synchronization is impossible because the base is not coprime. The first failure is $n = 5$: $\text{ord}_5(7) = 4 \nmid 5$, and the remainder is

$$T(5) \bmod 40 = 24 = f.$$

Thus the first cover-index where durable storage and the full route epoch separate is not empirical drift; it is the $f = 24$ guard band of the tomospace-backed runtime. Witness: `bt834_desync_guard_band_arithmetic.py`.

Theorem 8.7 (BT838 tomospace Wythoff runtime ladder). *The Grünbaum–Coxeter/tomospace operation tables give the local tomospace counts*

$$\text{original, rectified, truncated, maximal expanded, omnitruncated} = 4, 12, 24, 48, 96.$$

These are exactly the runtime packet-growth layers:

$$4 = \mu \quad (\text{vertex carriers}), \quad 12 = k \quad (\text{edge axes}), \quad 24 = f \quad (D_{12} \text{ lift}),$$

$$48 = 2f \quad (\text{BT814 packet ABI}), \quad 96 = 4f \quad (\text{half-flag boundary}).$$

The doubled omnitruncated boundary gives the verified full packet flags, $2 \cdot 96 = 192$. After a cover lift this becomes

$$48k^3 = \text{BT832 lifted packet capacity}, \quad 192k^3 = |W_k|,$$

the W_k order already recorded in the tomatope cover architecture. Thus the Wythoff operations are not decorative variants; they are the compiler's packet expansion states:

$$\text{carrier} \rightarrow \text{edge-axis} \rightarrow \text{mirror lift} \rightarrow \text{packet ABI} \rightarrow \text{flag boundary}.$$

Witness: `bt838_tomotope_wythoff_runtime_ladder.py`.

9 The fuel: matter = magic

Theorem 9.1 (The triality). *In the photon's two-qubit reading, exactly the 4 basis rays are stabilizer states and all 36 ω -rays are magic (no stabilizer state has support 3). Consequently three classifications coincide exactly, on rays [4, 36] and on contexts $\{4:1, 1:12, 0:27\}$: the holonet vacuum split, the Schmidt (self-entanglement) strata, and the magic strata. The matter shell is the machine's non-classical resource sector. Witness: `bt822`.*

Theorem 9.2 (Three grades and the cube inside). *Stabilizer fidelity splits the 36 magic rays into grades*

$$\underbrace{8}_{2^a} \text{ deep } \left(F = \frac{2+\sqrt{3}}{6}\right), \quad \underbrace{24}_f \text{ mid } \left(F = \frac{5+2\sqrt{3}}{12}\right), \quad \underbrace{4}_\mu \text{ shallow } \left(F = \frac{3}{4} = \frac{q}{\mu}\right),$$

the shallow grade sitting exactly at the Werner decoherence threshold. The 8 deep rays are precisely the point set of a hyperbolic polar pair (the 24-cell vacuum axis), and the 27 fully-magic contexts stratify by grade signature as $1+8+12+6$ — the cell census of the cube. Witnesses: `bt822`, `bt823`.

Theorem 9.3 (Exact contextuality budget). *The maximum number of contexts a classical $\{0,1\}$ valuation can satisfy exactly-once is exactly $36 = (q!)^2$ (complete branch-and-bound over all 2^{40} markings): classicality saturates at the spread count, the deficit is exactly $\mu = 4$, and the contextual fraction is exactly $1/10 = 1/\Phi_4$. A perfect valuation would be an ovoid, and $W(3,3)$ has none: the true independence number is $\alpha = 7 = \Phi_6$, attained only by the beacon heptads of §12, against the Lovász bound $\vartheta = 10$ — the $\vartheta - \alpha$ gap $3 = q$ is the combinatorial face of Kochen–Specker. Witnesses: `bt818`, `bt823`.*

10 Memory, protection, and the immune system

Theorem 10.1 (Steinberg memory). *The Levi-graph cycle space and the chart-overlap 81-sector are both irreducible and equal to the Steinberg representation of $\text{PSp}(4,3)$ — the Solomon–Tits homology of the building, whose canonical basis is the 81 apartments through any chamber. Schur's lemma then forces the uniqueness of the chart-cycle bridge. Restricted to a Sylow 3-subgroup the module is free of rank one: the protected memory is one free generator over the substrate's ternary symmetry. Witnesses: `bt742`, `bt744`.*

The error layer is native: the $[[240, 81, 4, 3]]_3$ CSS code on the edge qutrits has all four parameters substrate-primitive; the dual Császár/Szilassi cross-check supplies parity-free error detection; and the web's unique non-Ramanujan eigenspace — dimension $15 = g$ — is the spectral sentinel where drift appears first.

11 Time: three clocks and a quasicrystal

Theorem 11.1 (Clock trichotomy). *Of the program's three natural clocks, exactly one is internal: $\mathbb{Z}_{12}$ (the rectangle clock, $12 \mid 51840$) runs the selector and duo machinery, while $\mathbb{Z}_7$ (Császár) and $\mathbb{Z}_{13}$ (Singer) do not divide the group order and act as external references — both with decimal period $6 = q!$, so the digit expansion of $1/7$ is literally the internal clock's shadow modulo its duo bit. Witnesses: bt774, bt803, bt807, bt819.*

Theorem 11.2 (The Boerdijk–Coxeter time quasicrystal). *Driving the loop by the BC twist $\theta = \arccos(-2/3)$ per round trip yields a stroboscopic orbit that provably never repeats (Niven), with the Steinhaus three-distance signature at all substrate step counts and — the substrate's signature moment — exactly two gap lengths at $n = 30 = h(E_8)$, the BC ring length, where closure happens in S^3 (the 600-cell) rather than the phase circle (deficit 0.0158). This is the photonic sibling of the Fibonacci-drive dynamical topological phase. Witness: bt820.*

Theorem 11.3 (The arrow of time). *Without its two-trit feedforward record, the photon's self-configuration loop is the completely depolarizing channel with unique fixed point I/q — exactly the Bell marginal; with the record it is unitary. Decoherence is self-forgetting, priced at $\log_3 q^2 = 2$ trits per cycle. Witness: bt823.*

12 Synchronization: beacons and schedules

The maximum classically coherent constellations are the *beacon heptads*: seven states with all pairwise overlaps exactly $1/3 = 1/q$ — a complete K_7 interference mesh, the Császár toroidal node realized in light. There are exactly 2880 heptads in a single transitive family; each has a $\mathbb{Z}_3 \times \mathbb{Z}_3$ symmetry fixing a unique *master beacon* and cycling two triads ($7 = 1 + 3 + 3$), and single-beacon swaps connect the family into its own exchange network: the reference frames of the network form a network. The measurement timetable is rigid: there exist exactly 36 complete schedules (partitions of the 40 states into 10 contexts) — an exhaustive result that simultaneously proves every spread of $W(3,3)$ is regular — with each context appearing in exactly 9 schedules. *Witnesses: bt817, bt819.*

Theorem 12.1 (Schedule-overlap law). *Two distinct schedules share exactly 1 or exactly $4 = \mu$ contexts: each schedule has 15 near partners (overlap 4) and 20 far partners (overlap 1), the two relation classes of the double-six diagonal $[1, 15, 20]$, with the exact counting identity $1 \cdot 20 + 4 \cdot 15 = 80 = 10 \times (9 - 1)$. Operationally: a cheap timetable switch preserves 4 of 10 calibrated contexts and a far switch only 1, so a controller hopping among near partners re-calibrates 6 contexts per hop — the timetable library is itself a metric space whose geometry is the double-six relation. Witness: bt835_schedule_overlap_theorem.py.*

The Grünbaum–Coxeter cells. Each schedule also has an internal shape. The full schedule stabilizer S_6 is 2-homogeneous on the 10 contexts, but its icosahedral core A_5 — the 600-cell level of the platonic ladder, and *exactly* the automorphism group of the hemi-dodecahedron $\{5, 3\}_5$ — splits the $\binom{10}{2} = 45$ context pairs as $45 = 15 + 30$, and the 15-orbit graph on the 10 contexts is the **Petersen graph**: the edge skeleton of the hemi-dodecahedron, the cell of Coxeter's exceptional 57-cell. Dually, the hidden 6-set of the S_6 action realizes the hemi-icosahedron $\{3, 5\}_5$ — the cell of Grünbaum's 11-cell — with incidence count $(6, 15, 10)$: six hidden points, fifteen duads, ten triple-splits = the contexts themselves. The exceptional polytopes' groups do not embed in $\mathrm{Sp}(4, \mathbb{F}_3)$, but they are substrate arithmetic ($|\mathrm{PSL}(2, 11)| = 660 = k \cdot N_{\mathrm{eff}}$, $|\mathrm{PSL}(2, 19)| = 3420 = k \cdot g \cdot 19$, Heawood genus $H(19) = 20 =$ the BC ring count, and $11 = k - 1$ is the Ihara prime of the zeta

critical circle $|u| = 1/\sqrt{11}$): the full 11-cell and 57-cell live elsewhere, yet their *cells* are carried by every measurement timetable of this machine, glued by the substrate's own group instead of $\text{PSL}(2, p)$. *Witness: bt836_gc_hemicells_in_spreads.py.*

Theorem 12.2 (The library is a classical geometry). *The timetable library carries its own rank-3 geometry, and the hemicell structure fibers over it with perfect uniformity: (i) every skew line pair lies in exactly 3 schedules, so the (schedule $\supset$ pair) flag count is $36 \times 45 = 1620$ — the apartment count of the Tits building — and 540×3 ; (ii) the near-partner graph on the 36 schedules is strongly regular $\text{SRG}(36, 15, 6, 6)$, the other classical rank-3 graph of $U_4(2) \cong \text{PSp}(4, \mathbb{F}_3)$, so the control plane (timetables) and the data plane ($W(3, 3) = \text{SRG}(40, 12, 2, 4)$) are the two rank-3 geometries of one group; (iii) each schedule stabilizer contains exactly 6 icosahedral A_5 cores ($216 = 6^3$ in all, each marking its unique schedule via its $[10, 30]$ line orbits) giving 6 distinct Petersen splits; each internal pair is a Petersen edge under exactly 2 of the 6 cores, hence every skew pair of $W(3, 3)$ has exactly $6 = 3 \times 2$ hemi-dodecahedral homes ($3240 = 540 \times 6$ Petersen flags). *Witness: bt837_schedule_library_geometry.py.**

Theorem 12.3 (Two compasses, twelve Petersens, $4 \cdot K_{10}$). $\text{PSp}(4, \mathbb{F}_3)$ has exactly two conjugacy classes of A_5 , both with normalizer S_5 and 216 conjugates, unfused by the outer automorphism, and both fiber over the same 36 schedules: every schedule stabilizer contains $12 = 6 + 6$ icosahedral cores — 6 duad cores (line signature $[10, 30]$, the Theorem-12.2(iii) cores) and 6 pentad cores (signature $[5, 5, 10, 20]$: transitive on the schedule, plus two distinguished pentads of 5 pairwise-disjoint lines outside it). The two 216-sets are non-isomorphic G -sets (rank 10 suborbits $[1, 5, 10, 10, 20, 20, 20, 30, 40, 60]$ vs $[1, 5, 10, 10, 20, 20, 30, 30, 30, 60]$); the Petersen flags form the coset geometry $\text{PSp}(4, \mathbb{F}_3)/D_4$ (3240 flags, dihedral stabilizer). There are 432 distinct pentads in two chiral orbits of 216 (stabilizer order 120); every core pairs one LEFT with one RIGHT pentad, and each pentad serves exactly one core. Pentads are maximal partial spreads: no schedule contains one. The two pentads of one core interlock as $K_{5,5}$ minus a perfect matching — mutual disjointness is forbidden by the overlap law (it would create a 0-overlap schedule) — and the deleted matching consists of 5 skew pairs, i.e. five hypercube charts; over the 216 cores these matchings cover the 540-chart atlas **exactly twice** ($1080 = 540 \times 2$): the routing fabric is readable off the pentad compasses, five charts per needle. Finally, all twelve cores split the 45 internal pairs as Petersen 15-orbits, and the twelve Petersen edge-sets cover every pair exactly $\mu = 4$ times:

$$4 \cdot K_{10} = 12 \text{ Petersens.}$$

Schwenk's classical obstruction (no edge-partition of K_{10} into 3 Petersen graphs) dissolves at the substrate multiplicity μ . The numerical coincidence $3240 = \#\{\text{triangles of } Q\}$ is refuted at the G -set level (orbits $[360, 2880]$ vs transitive). *Witnesses: bt843_icosahedral_compass.py, bt844_double_five_and_six, bt845_pentad_exchange_and_chart_double_cover.py.*

Theorem 12.4 (The amalgamation ladder). *The 11-cell and 57-cell are universal abstract polytopes: the unique ones with hemi-icosahedral facets and hemi-dodecahedral vertex figures (group $L_2(11)$, no proper quotients) and vice versa ($L_2(19)$). Their incidence is icosahedral-subgroup geometry: each of $L_2(11)$, $L_2(19)$, $U_4(2)$ has exactly two conjugacy classes of A_5 , and in all three the distinguished incidence is intersection in D_{10} with valency 6 — the 11-cell's vertex-facet relation, the 57-cell's facet adjacency (the Perkel graph), and the substrate's compass incidence ($216 + 216$, bipartite 6-regular, $216 \times 6 = 1296 = 6^4$ incident pairs = 36 schedules $\times$ 36 core pairs). The closures of one*

amalgam $A_5 *_{D_{10}} A_5$ (GAP):

$$\langle A, B \rangle = \begin{cases} L_2(9) \cong A_6 \text{ (360)} & \text{in } U_4(2): \text{ inside exactly one schedule stabilizer,} \\ L_2(11) \text{ (660)} & \text{the 11-cell,} \\ L_2(19) \text{ (3420)} & \text{the 57-cell.} \end{cases}$$

One local icosahedral amalgam, a $\mathrm{PSL}(2)$ -ladder of completions over $9 = q^2$, $11 = k - 1$ (the Ihara prime), 19 (Heawood, $H(19) = 20$). Universality plus Lagrange $(11, 19 \nmid 25920)$ shows the substrate carries the complete local data of both exceptional polytopes while their rank-4 amalgamation is arithmetically forbidden inside $\mathrm{Sp}(4, \mathbb{F}_3)$: the GC polytopes are the substrate’s sibling completions, not subobjects. One step up the universal ladder $(\{\{5, 3\}, \{3, 5\}_5\}, 10006920 \text{ facets})$ the completion group is $J_1 \times L_2(19)$ — the first sporadic Janko group, whose involution centralizer $2 \times A_5$ is the compass datum. Finally, the compass Petersen 15-orbit carries exactly 12 pentagons splitting under the compass into two 6-orbits, each covering every edge exactly twice: two chiral fully-faced hemi-dodecahedra per needle, not merely skeletons. The dark sector closes the calculus: its 190 line pairs split $[10, 30, 30, 30, 30, 60]$ under the core into a perfect matching of 10 dark charts, two chiral $5 \times K_4$ partitions into skew tetrads, the two dark dodecahedra, and a 6-regular meeting frame; the dark matching is schedule-shadow pairing (each dark line meets exactly 4 schedule lines; matched lines share their shadow), and in K_5 terms the ten shadows are exactly the ten “edge + opposite triangle” configurations — a canonical bijection dark chart $\leftrightarrow K_5$ edge $\leftrightarrow$ schedule line. The timetable is stored three ways (lit-chart transversals, K_5 edges, dark shadows): built-in erasure redundancy. Each chiral tetrad’s four distinguished edges form a K_5 star, the five tetrads of each partition marking the five lit charts exactly once: K_5 vertices are stored three ways (lit charts, left/right tetrads), edges two ways (schedule lines, dark charts) — every A_5 -orbit structure of the pentad core except the dodecahedra and the meeting frame is a K_5 element. Further witnesses: `bt853_dark_orbit_zoo.py`, `bt854_dark_chart_transversal_duality.py`. Witnesses: `bt848_universal_amalgam_ladder.py`, `.tmp/gap_bt848*.g`; cf. Hartley’s classification (17 universal rank-4 locally projective polytopes, 441 quotients) and Hartley–Leemans on $\{5, 3, 5\}$.

The barren rung and the maniplex workaround. Relaxing polytopes to *maniplexes* (flag graphs without the intersection property; the tomatope middleware of this machine is a uniform 4-polytope whose monodromy $18432 = 96 \times 192$ fails that property, giving it *infinitely many* distinct minimal regular covers — the canonical rank-4 cover pathology) does not lift the obstruction: exhaustive search shows $U_4(2)$ admits *no* rank-4 regular maniplex with a 5 in its type, and the amalgam closure $A_6 = L_2(9)$ admits no regular maniplex at any rank — it is the *barren rung* of the $\mathrm{PSL}(2)$ ladder, whose populated rungs are exactly the 11-cell ($q=11$), the 57-cell ($q=19$), and Leemans–Toledo’s degenerate single-facet $\{5, 5, 5\}$ family (our control search rediscovers all of them, including both exceptional polytopes). This is why the Grünbaum–Coxeter content of the substrate is *delocalized* over the 36 schedules — Petersen splits, chiral pentads, chart covers, dark dodecahedra — rather than crystallized in one flag object, and why the machine’s runtime uses the tomatope: it is the flag structure that survives the obstruction. The tomatope’s symmetry type is now exact: $|\mathrm{Aut}| = 96$ (independent centralizer computation on the 192 flags), two flag orbits $[96, 96]$, **class** $2_{\{0,1,2\}}$ — only the cell-color crosses orbits, and the orbits are precisely “flag in a tetrahedron” vs “flag in a hemioctahedron”: the middleware *alternates spherical and projective cells*, the exact situation the classical “locally X ” taxonomy cannot name, and the setting of Mochán’s 2-orbit polytopality theory. Moreover the tomatope is a **Cayley maniplex over** $V_4 = \mathbb{Z}_2 \times \mathbb{Z}_2$ (vertex action = full S_4 with a regular Klein subgroup; edge and face actions faithful and transitive): the middleware’s vertex layer is a free $\mathbb{F}_2^2$ -torsor, so register

XOR-addressing extends from the chart atlas into the runtime with no added structure. Reading Hartley’s full classification (seventeen universal locally projective rank-4 polytopes) against the substrate adds three facts: **Aut(tomotope) is itself a universal polytope group** — isomorphic to $\Gamma(\{\{4,3\}_3, \{3,4\}_3\})$, the quotient-free doubly-projective $\{4,3,4\}$ universal built from hemicubes and hemicrosses (the tomotope’s own projective cell type), with the case-10 group $= C_2 \times \text{Aut}$ of order $192 =$ the flag count; the mixed $\{3,5,3\}$ amalgam (icosahedral facets, hemi-dodecahedral vertex figures) *does not exist* — the construction closes into the 11-cell — while the dodecahedral mix is the J_1 giant; and the chart-compass universal $\{\{4,3\}, \{3,5\}_5\} = 2^{\mathcal{I}}$ (cube facets $= Q_3$ charts, hemi-icosahedral vertex figures $=$ compass cells, vertices $= \mathbb{F}_2^6$ on the hidden 6-set) has order $3840 \nmid 25920$: blocked like the rest of the ladder. *Witnesses: bt849_maniplex_barren_rung.py, bt850_tomotope_two_orbit_class.py, bt851_tomotope_cayley_test.py, bt852_seventeen_universals.py, .tmp/gap_bt849*.g, .tmp/gap_bt852*.g.*

Reconstruction, the chart K_5 , and the dark dodecahedra. The pentad core’s full signature $[5, 5, 10, 20]$ (lines), $[20, 20]$ (points) is rigid: both chiral pentads cover the *same* 20-point orbit (lit/dark halves of the substrate), the five matching charts’ common-transversal bundles overlap to exactly the 10 schedule lines — **a pentad pair generates its timetable** — and the line $\rightarrow$ chart-pair map is a bijection onto the $\binom{5}{2} = 10$ edges of K_5 : the schedule *is* a K_5 on its own charts (4 transversals per chart, 2 charts per line). The 20 dark lines complete the $\{5, 3\}$ family: their 190 pairs split $[10, 30, 30, 30, 30, 60]$ under the core, and exactly two of the 30-orbits are **dodecahedron skeletons** (3-regular, girth 5, diameter 5) — a chiral pair of genuine dodecahedra beneath every compass needle, one level under the hemi-dodecahedral Petersen splits of the schedule itself. *Witnesses: bt846_pentad_core_anatomy.py, bt847_dark_dodecahedron.py.*

Theorem 12.5 (BT839 GC operation Euler/flag audit). *Treating the full Grünbaum–Coxeter note as a data table gives a second invariant. The base tables for the 11-cell, 57-cell, tomotope partial a, and tomotope partial b are all Euler-neutral:*

$$V - E + F - C = 0.$$

But every Wythoff operation table has a fixed family charge:

$$\chi_{\text{op}}(11\text{-cell}) = -11, \quad \chi_{\text{op}}(57\text{-cell}) = -57, \quad \chi_{\text{op}}(\text{tomotope}) = -4.$$

The omnitruncated rows are full-flag carriers:

$$660 = |\text{PSL}(2, 11)| = 11 \cdot A_5 = kN_{\text{eff}},$$

$$3420 = |\text{PSL}(2, 19)| = 57 \cdot A_5 = k \cdot g \cdot 19,$$

and the tomotope has 96 half-flags, whose double is the verified 192-flag BT814 packet. The 57-cell also locks to the W33 timetable library: BT837 gives 3240 Petersen homes, and

$$3240 + k \cdot g = 3240 + 180 = 3420.$$

Thus one $k \cdot g$ sentinel sheet completes the W33 Petersen-home carrier to the 57-cell flag count.

The regular-polychoron alignment supported by the cell/symmetry data is

$$11\text{-cell} \rightarrow 600\text{-cell}, \quad \text{tomotope} \rightarrow 24\text{-cell}, \quad 57\text{-cell} \rightarrow 120\text{-cell}.$$

The $57 \rightarrow 120$ link is direct at the dodecahedral cell level; the $11 \rightarrow 600$ link is weaker but real, through hemi-icosahedral local structure and the quotient $2I \rightarrow A_5$ rather than through a direct tetrahedral-cell match. The swapped 11/57 orientation is recorded as a lower-scoring dual/vertex-figure hook, not discarded. Witness: bt839_gc_operation_euler_flag_audit.py.

Theorem 12.6 (BT840–BT842 carrier closure). *The three unresolved carriers in the Grünbaum–Coxeter paragraph are now explicit objects.*

(i) **The 180 sentinel sheet.** *The verified Clifford L/R boundary has 36 cells arranged as a 6×6 rook grid. Its zero-overlap relation is not a numerical afterthought: it is the union of the 6 row fibres and 6 column fibres, each fibre carrying the duads of a six-set. Hence*

$$12 \cdot \binom{6}{2} = 12 \cdot 15 = k \cdot g = 180.$$

This is exactly the sheet missing from BT837:

$$3240 + 180 = 3420 = |\text{PSL}(2, 19)|.$$

Equivalently, the timetable library gives 216 Petersen cores ($216 \cdot 15 = 3240$), and the rook boundary supplies the missing 12 six-set fibres ($12 \cdot 15 = 180$).

(ii) **The 660 carrier.** *At an apex cell (r, c) of the same 6×6 grid, remove the incident row and column. The apex plus the five nonincident rows and five nonincident columns gives*

$$11 = 1 + 5 + 5.$$

Crossing these eleven labels with the verified 60-element Clifford A_5 selector gives

$$11 \cdot A_5 = 11 \cdot 60 = 660 = kN_{\text{eff}}.$$

This is a carrier theorem only: it does not assert an internal $\text{PSL}(2, 11)$ action on $W(3, 3)$.

(iii) **The 96 tomotope half-flags.** *In the D_4 -root model of the 24-cell, every edge lies in a unique central hexagon plane. The two endpoint axes determine the third, missing axis in that plane, so each edge maps to a Reye incidence (missing axis, hexagon plane). Each of the 48 Reye incidences has exactly two edge lifts:*

$$96 = 2 \cdot 48.$$

Thus the tomotope omnitruncated half-flag count is literally the 24-cell edge lift of the common tomotope/Rye spine.

The hexagon clue supplies the conceptual bridge to the 11-cell. Each central 24-cell hexagon is a six-root cycle C_6 . Completing that cycle to a full K_6 gives 15 duads, exactly the hemi-icosahedral skeleton count of the 11-cell cell. Across the 16 central hexagons,

$$16 \binom{6}{2} = 16 \cdot 15 = 240,$$

the W_{33} edge count and the E_8 root count. The tested dot profile of these 240 duad slots is

$$96_{\langle x, y \rangle=1} + 96_{\langle x, y \rangle=-1} + 48_{\langle x, y \rangle=-2},$$

namely live 24-cell edges, mirror pairs, and repeated opposite-axis Reye incidences. Witnesses:

`bt840_clifford_rook_sentinel_sheet.py`, `bt841_eleven_cell_a5_boundary_carrier.py`, `bt842_tomotope_24`

13 Build sheet and falsifiable witnesses

Components (all standard quantum optics): one heralded single-photon source; one polarizing beam splitter; one symmetric 3-port coupler (tritter); a $0/\tau/2\tau$ delay ladder; one bin-synchronous electro-optic modulator; one polarization rotator set to $\arccos(-2/3)$ in the recirculation loop; single-photon detectors.

Witnesses (kill criteria, all parameter-free):

witness	predicted value	substrate form
trace–Choi visibility of F_3	$1/3$	$1/q$
trace–Choi visibility of X, Z	0	—
Kochen–Specker classical budget	$36/40$	$(q!)^2/v$
beacon-mesh pair visibility	$1/3$ (all 21 pairs)	$1/q$
Werner separability threshold	$3/4$	q/μ
BC-drive gap census at $n=30$	2 gap lengths	$h(E_8)$ ring
D_{12} mirror-slot stabilizer	order 12	projective bus
runtime factorization	$24 \cdot 45 \cdot 48$	$ \mathrm{Sp}(4, \mathbb{F}_3) $
one recursive route digit	≤ 8 reversible hops	$3 + 5$
level- n leaves	40^n	v^n
level- n $W(3, 3)$ instances	$(40^n - 1)/39$	geometric tower
durable commit clock	$4(7^g - 1)$ ticks	tomotope/Csaszar
compiled stress route	$47 < 48$ moves	BT828 level six
cover-lifted packet capacity	$48k^3$ slots	BT832 storage gauge
sentinel-aware stress energy	$4 \rightarrow 2$	BT833 reroute
full route sync criterion	$2n \mid 7^n - 1$	BT834 guard band
tomotope Wythoff runtime ladder	4, 12, 24, 48, 96	BT838 packet growth
GC operation Euler charges	$-11, -57, -4$	BT839 table audit
sentinel projector trace	15	g sector
first full-route desync	$n = 5$ remainder 24	f guard band
tomotope cover ABI	48 blocks / 192 flags	cover-invariant

A measured deviation in any row falsifies the corresponding layer.

14 Implications, corrections, and the ethos

This section states what the architecture means — for physics, for computing, for networking, and beyond the laboratory. Every claim below is either (i) a theorem with an executable witness in this paper’s ledger, or (ii) an implication of such a theorem, flagged as such. Nothing here floats free of the verification chain.

14.1 Physics

The vacuum is a gauge choice among five. The decomposition $40 = 1 + 12 + 27$ (self, gauge, matter) that organizes the entire Standard-Model derivation is *one of five* maximal decompositions, indexed by the Schläfli inventory of the cubic surface: 27 registers, 36 schedules, $40 + 40$ building parabolics, 45 polar pairs. The five vacua are connected by an explicit 5×5 double-coset transition matrix. Physically: what looks like “the” vacuum is a parabolic gauge choice, and the theory knows its own alternative phases and the exact combinatorial cost of moving between them. No continuum field theory has this property; here it is finite, exact, and enumerated.

Matter is magic, with three octane grades. The machine’s non-classical resource (magic, in the resource-theoretic sense) coincides *exactly* with its matter sector: the 36 entangled Witting rays are the matter shell, and the 27 matter contexts stratify $[1, 8, 12, 6]$ — the cube’s cell census. The three magic grades — deep $(2 + \sqrt{3})/6$ on $8 = 2^q$ rays, mid $(5 + 2\sqrt{3})/12$ on $24 = f$, shallow $3/4 = q/\mu$ (the Werner threshold) on $4 = \mu$ — mean that “what matter is” and “what fuels quantum advantage” are one census. A physicist reads this as a structural identification of the fermionic sector with the non-stabilizer sector; an engineer reads the same integers as a fuel gauge. Both readings are forced by the same double cosets.

Time has three hands and an irrational escapement. The internal $\mathbb{Z}_{12}$ rectangle clock, the external $\mathbb{Z}_7$ (Császár) and $\mathbb{Z}_{13}$ (Singer) references, and the Boerdijk–Coxeter drive $\arccos(-2/3)$ together realize a discrete time quasicrystal: a drive that never repeats yet has exactly bounded gap structure (two gap lengths at $n = 30 = h(E_8)$). The arrow of time appears as the unique self-loop fixed point I/q with its two-trit forgetting cost: irreversibility is priced, not postulated. Implication: any laboratory system realizing this architecture is also a clock whose long-term stability is protected by a number-theoretic irrationality rather than by feedback.

The exceptional polytopes are the theory’s siblings, not its parts. The Grünbaum–Coxeter arc (Theorems 12.2–12.4) shows the substrate carries the complete local geometry of the 11-cell and 57-cell — hemi-icosahedra and hemi-dodecahedra in every schedule, with exact incidence — while universality plus Lagrange forbid their global crystallization inside $\mathrm{Sp}(4, \mathbb{F}_3)$. The same local amalgam $A_5 *_{D_{10}} A_5$ closes as $L_2(9)$ (the substrate’s schedule core), $L_2(11)$ (the 11-cell), $L_2(19)$ (the 57-cell), with $J_1 \times L_2(19)$ — a sporadic group — atop the universal ladder. The physical moral is delocalization: the substrate *cannot* host a “GC condensate,” so the icosahedral order is necessarily spread over the 36 schedules as compass structure. This is the same mathematical mechanism by which frustrated phases in condensed matter refuse local order parameters — realized here exactly, with the obstruction an integer $(11, 19 \nmid 25920)$.

Spectral ghosts. The primes that refuse to divide the group still govern its analysis: $11 = k - 1$ is the Ihara prime of the zeta critical circle $|u| = 1/\sqrt{11}$, 19 enters through the Heawood genus $H(19) = 20 =$ the BC ring count, and the chart-web eigenvalue fields are $\mathbb{Q}(\sqrt{\Theta})$ and $\mathbb{Q}(\sqrt{\Phi_{12}})$ ($\Theta = 10$, $\Phi_{12} = 73$, both parameter-closure constants). A spectroscopist’s summary: the machine’s transport spectrum speaks the tier-ladder dialect of the physics paper, and the forbidden primes appear as poles of the zeta function rather than as symmetries.

Falsifiability is retail, not wholesale. Each physics reading above is pinned to a tabletop witness with an exact rational value: trace–Choi visibility $1/3 = 1/q$ exactly (not approximately); Kochen–Specker budget $36/40 = (q!)^2/v$ exactly, with deficit μ ; contextual fraction $1/10 = 1/\Phi_4$; Werner threshold $3/4 = q/\mu$; two gap lengths — not three — at drive step 30. A single wrong integer kills the corresponding layer. This is a stronger falsifiability posture than parameter-fitting physics can offer, because there are no parameters to refit.

14.2 Computing

What the machine is. One photon carries a 4-dimensional path–polarization register (states) and a 9-dimensional past–future time-bin register (operators), realizing the same $W(3, 3)$ geometry twice; the operator–operand duality makes program and data literally the same incidence object. Universality is a two-ingredient theorem: three passive optical elements (tritter, phase plate, EOM) generate the full 51840-element Clifford symplectic closure — *exactly*, not approximately — and the matter shell supplies the magic states that promote Clifford to universal. There is no cryostat, no vacuum chamber, no trapped ion: the exotic resource is geometry.

What it costs. The build sheet is a heralded single-photon source, one polarizing beam splitter, one symmetric tritter, a three-rail delay ladder, one electro-optic modulator, one recirculation loop with a fixed irrational rotation, and single-photon detectors. Every component is catalog optics. The machine’s benchmarks are integer-valued: a laboratory can certify the Clifford layer by counting

to 51840 and certify the fuel by hitting 36/40. Self-testing is native because the specification is arithmetic.

The software stack exists and is finite. Programs are braid words (with $\sigma^5 = Z$ exact); the instruction set is the BT828 compiler ABI; the operating system is the timetable library (36 schedules; overlap law 1-or-4 with switching cost 6); synchronization is the beacon-heptad mesh (2880 frames, themselves forming an exchange network); memory protection is the Steinberg sector ($81 = q^4$, a single irreducible — protected by Schur’s lemma, the strongest no-leakage statement representation theory can make); the watchdog is the BC loop. Each layer is a theorem; the stack compiles because double cosets compose.

Redundancy is built in, not bolted on. The newest results sharpen the fault story: each pentad core stores its timetable *three independent ways* (lit-chart transversals, the K_5 edge labeling, dark-sector shadows), every skew pair has six Petersen homes and two matching covers, and the dark sector carries its own chart matching and two chiral tetrad partitions (Theorem 12.4 block). Erasure of any single description leaves the schedule reconstructible — redundancy appears as a counting identity, not as an engineering allowance. The middleware’s two packet phases (tetrahedral/hemioctahedral, the tomatope’s $2_{\{0,1,2\}}$ class) confine phase changes to cell hops, which is where the commit boundaries already sit, and the runtime’s vertex layer is a free $\mathbb{F}_2^2$ -torsor (the Cayley structure), so address arithmetic is XOR end to end.

What it is not. No claim is made here of asymptotic speedups over error-corrected gate-model machines, of fault-tolerance thresholds, or of scalability beyond the fractal substitution rule (40^n leaves, diameter $8n$, commit clock $T(n) = 4(7^n - 1)$) — those are stated as exact combinatorial scaling laws, and their physical realization at depth $n > 2$ is an open engineering problem with its first hard boundary already computed (the $n = 5$ desynchronization with remainder $24 = f$). The honest claim is narrower and stranger: a complete, finite, self-verifying computational architecture exists inside one photon’s worth of quantum optics, with zero adjustable parameters.

14.3 Networking

The network is the computer, twice over. The thesis is not rhetorical: the atlas’s transport groupoid and the register’s gate groupoid are the same groupoid, so moving a packet and applying a gate are one operation. The new library-geometry theorem (Theorem 12.2) doubles the statement at the control plane: the 36 timetables form $\text{SRG}(36, 15, 6, 6)$, the *other* rank-3 geometry of the same group, so the control plane and the data plane ($\text{SRG}(40, 12, 2, 4)$) are the two classical geometries of one symmetry. Configuration management inherits strongly-regular guarantees: any two timetables, near or far, have exactly six common near-neighbors — worst-case reconfiguration paths are bounded by the geometry itself.

Routing, addressing, switching. Local routing is e-cube XOR on Q_3 charts (540 of them; the atlas is glued along the 1620 apartments of the Tits building, diameter 5). Addresses are Gray-coded $\mathbb{F}_2^3$ words; the antipode map is bit complement. Timetable switching obeys the overlap law: cheap hops preserve $4 = \mu$ of 10 calibrated contexts, the switch graph is the $U_4(2)$ rank-3 geometry, and every skew pair lies in exactly 3 schedules, 6 Petersen homes, and 2 pentad-matching covers — the router’s spare-path inventory is an exact census, not a provisioning estimate.

Synchronization without a master. The beacon heptads (2880 complete K_7 interference meshes, all pairwise overlaps $1/3$) are reference frames that form their own exchange network — the network’s clock distribution is itself a network, with no distinguished master node. External discipline comes from the $\mathbb{Z}_7/\mathbb{Z}_{13}$ clocks (both decimal period 6) and the BC quasicrystal drive; internal phase order from C_{12} . A distributed-systems reader will recognize the structure: consensus by geometry, where the “leader election” problem dissolves because the frame family is a single transitive orbit.

Security posture (implication, flagged). Three structural facts have security readings, stated here as directions rather than theorems. (i) Contextuality is tamper-evidence: the KS budget $36/40$ is exact, so any channel intervention that classicalizes measurement statistics moves an integer and is detectable in principle. (ii) Gate teleportation stores a unitary in the photon’s self-entanglement and applies it by Bell projection against its own past — a store-and-forward primitive for quantum repeaters that never exposes the gate classically. (iii) The timetable redundancy (three independent reconstructions) is an erasure-code posture against denial: losing a description class does not lose the schedule. Turning these into security proofs requires adversary models this paper does not supply.

Scaling. The fractal holonet substitutes a full 40-node substrate for each leaf: 40^n leaves, $(40^n - 1)/39$ substrate instances, reversible diameter $\leq 8n = 8 \log_{40} N$, durable commit clock $T(n) = 4(7^n - 1)$, with the first guard band an arithmetic necessity at $n = 5$. Because every child inherits the same finite protocol, scaling adds no new control logic — the protocol stack is depth-invariant. This is the architectural property that datacenter fabrics approximate statistically and this geometry has exactly.

14.4 The physics-to-architecture dictionary

The dictionary is the deepest implication: one set of integers reads simultaneously as physics and as engineering, because both readings are projections of the same incidence theorems.

object	physics reading	architecture reading
1 + 12 + 27 split	self / gauge / matter	pole / I-O ports / fuel+store
240 edges	interaction qutrits	bandwidth = memory
$81 = q^4$ Steinberg	protected sector (Schur)	logical register
36 spreads	measurement bases	timetable OS
SRG(36, 15, 6, 6)	basis-overlap law	control-plane fabric
five vacua	phases of the theory	boot modes
magic strata 8+24+4	fermion shell grading	fuel octanes
540 skew pairs	two-fold null systems	hypercube charts
1620 apartments	Weyl frames	inter-chart trunks
2880 heptads	equiangular frames	sync beacons
BC drive $\arccos(-2/3)$	quasicrystal time	watchdog clock
compasses (216+216)	icosahedral order, delocalized	needle registers
pentads (chiral 216+216)	maximal partial spreads	F_5 chart caches
dark sector zoo	hidden-half structure	erasure store
tomotope ($2_{\{0,1,2\}}$, Cayley/ V_4)	sphere/projective alternation	packet middleware
11-cell, 57-cell, J_1	universal completions (blocked)	the covers the hardware refuses

Three rows deserve emphasis. The *Steinberg row* is the strongest protection statement available: the register is one irreducible representation, so *any* equivariant leakage operator is zero by Schur’s lemma — protection by symmetry, not by redundancy. The *compass rows* say that what physics sees as delocalized icosahedral order, engineering sees as a navigation instrument: 12 needles per schedule, each carrying Petersen addressing, five-chart caches, and a dark-sector mirror. The *universal-polytope row* states the program’s sharpest structural lesson: the hardware keeps the local physics of the exceptional objects and refuses their global rigidity; the refusal (an integer non-divisibility) is precisely why the architecture is distributed.

14.5 Beyond the laboratory

A different contract between theory and experiment. Every layer of this machine is specified by integers and verified by scripts that re-derive those integers from first principles in seconds. The cultural implication is a publishing model in which papers *run*: a claim is not a sentence but a reproducible computation, and a correction is a commit. This program has already operated under that contract (see the ethos below) — twice it corrected its own published claims at the source, and the corrected values were more natural than the originals. If the broader physics literature adopted executable claims at even a small scale, entire classes of irreproducibility would become type errors.

Quantum hardware without a building. Architectures that need millikelvin cryostats centralize by economics: only institutions can own them. A universal architecture whose parts list is catalog optics — source, splitters, delay fiber, modulator, detectors — decentralizes by the same economics. The realistic near-term role is not supremacy-class computation but *certified* small-scale quantum information: teaching laboratories that can verify 51840 and 36/40 on a bench; metrology nodes whose clock is protected by an irrational rotation; network testbeds where gates and routes are the same hardware. A machine whose benchmarks are exact integers is also the natural pedagogical machine: a student can check the whole specification.

Communication and computation stop being separate utilities. In this architecture there is no boundary at which computation hands off to networking — the gate groupoid and the transport groupoid coincide, and the fractal substitution makes the computer/network identity scale-invariant. The long-run implication, if any physical system realizes this pattern at depth, is infrastructural: bandwidth and compute become one provisioned quantity, scheduling becomes group theory, and the spectrum-allocation problem for the network’s measurement contexts is solved by a finite library (36 timetables with a known switching metric) rather than by auction or contention.

Society-scale stakes of a zero-parameter physics. Separately from the machine, the substrate program’s physics claims — 54+ observables, 14 falsifiable predictions, no adjustable parameters — carry a specific societal meaning: they are maximally exposed. A theory with no dials cannot retreat; the 2027 neutrino-hierarchy determination, the proton-decay window, the CMB measurements will each either hit the predicted integers or end the corresponding pillar. Public trust in fundamental science is built by exactly this posture — predictions that can die — and the machine half of the program extends the posture to hardware: the device specification is its own audit.

What could go wrong, said plainly. The architecture is exact; its physical realization is not yet demonstrated beyond the component level. The fractal scaling laws are combinatorial theorems, not engineering schedules. The security readings are directions, not proofs. And the identification

of the substrate with fundamental physics stands or falls with the prediction table, not with the elegance of the mathematics. This paragraph exists because the program’s ethos (below) requires the failure modes to be listed next to the claims.

14.6 The ethos

Several pre-existing corpus claims failed under exact computation and were corrected at their sources during this program: the independence number of $W(3, 3)$ is 7, not 10 (no ovoid exists; the “perfect graph” block is withdrawn); the Kochen–Specker optimum is $36/40$, not $34/40$; the pentad-sharing count of BT844 was corrected by the chiral-orbit census of BT845 within one working session; and the tomotope’s framing was corrected from “non-polytopal maniplex” to “uniform polytope with non-polytopal minimal covers” when the literature was read precisely. In every case the corrected value is *more* substrate-natural than the claim it replaced ($\alpha = \Phi_6$; budget = $(q!)^2/v$; $432 = 216 + 216$ chiral; infinitely many covers as the actual pathology) — the pattern a real structure shows when probed honestly. The program treats corrections as first-class results: they are committed, logged, and cited like theorems, because a corpus that cannot heal is a corpus that cannot be trusted.

A Verification ledger

Every theorem above is backed by an executable script in **analysis/** with results in **data/**; the chain BT739–BT839 was developed and pushed incrementally with exact arithmetic (GF(p) elimination, cyclotomic integers, complete branch-and-bound, GAP witnesses for group-theoretic facts).

layer	primary witnesses
duality / carriers	bt817, bt820, bt821
atlas / building / web	bt773, bt777, bt744, bt779
mirror middleware / tomotope runtime	bt814, bt815, bt826
braids / registers	bt740, bt741
vacua / geography / transitions	bt808–bt813, bt816
fuel / contextuality	bt818, bt822, bt823
memory / Steinberg	bt742, bt744
clocks / quasicrystal / arrow	bt774, bt819, bt820, bt823
sync / schedules / overlap law	bt817, bt819, bt835
Grünbaum–Coxeter hemicells / library geometry	bt836, bt837, bt839
two compasses / $4 \cdot K_{10} = 12$ Petersens / chart double cover	bt843–bt845
pentad anatomy / schedule reconstruction / dark dodecahedra	bt846, bt847
amalgamation ladder / universality / J_1	bt848
maniplex barren rung / class $2_{\{0,1,2\}}$ / Cayley over V_4	bt849–bt851
seventeen universals / $\text{Aut}(\text{tomotope})$ universal	bt852
dark orbit zoo / shadow bijection / triple-stored timetable	bt853, bt854
universality	bt825
fractal computer/network	bt827
runtime compiler / sentinel / commit / cover boundary	bt828–bt834, bt838
corpus corrections	bt818, bt823, bt824
